Abstract
Formation of unstable plaques frequently results in atherothrombosis, the major cause for ischaemic stroke, myocardial infarction and peripheral arterial disease. Patients who have symptomatic thrombosis in one vascular bed are at increased risk of disease in other beds. However, the development of the disease in carotid, coronary and peripheral arteries may have different pathophysiology suggesting that more complex treatment protocols may have to be designed to reduce plaque development at different locations. In this review we describe the known risk factors, compare the developmental features of coronary and carotid plaque development and determine their association with end-point ischaemic events. Differences are also seen in the genetic contribution to plaque development as well as in the deregulation of gene and protein expression and cellular signal transduction activity of active cells in regions susceptible to thrombosis. Differences between carotid and coronary artery plaque development might help to explain the differences in anatomopathological appearance and risk of rupture.

Introduction
Atherothrombosis is the major causative agent for ischaemic stroke (IS), myocardial infarction (MI) and peripheral arterial disease (PAD). Patients having symptomatic thrombosis in one vascular bed are at increased risk of disease in other beds [1]. Patients presenting with cerebral ischaemic events have a 5-year risk for MI of 10–25% and for non-stroke vascular death of 10–15% [2]. The risk of a second atherothrombotic event is increased after the occurrence of a first MI or stroke. A second MI occurs

M. Slevin and J. Krupinski contributed equally to this paper.
within 6 years of the first in 23% of men and 31% of women. Within 6 years of a first MI, IS occurs in 9% of men and 18% of women. The risk of a recurrent stroke within 1 year of an initial stroke is 10–12% [3] and the risk of MI is 7% [4]. These risks are 5–10 times higher than those for the general population and furthermore, patients with mural plaques and accelerated platelet aggregation, even when asymptomatic, have a poor prognosis [5, 6]. Common and different features in coronary and carotid artery disease are discussed and some more important aspects are listed in Table 1.

Coexistence of Coronary Artery Disease and Carotid Artery Disease

Many studies have shown a relationship between coronary artery disease (CAD) and carotid artery disease. In the majority of patients suffering from IS, significant CAD is also present. For example, clinical trials have shown that 20–30% of subjects with ischaemic heart disease also had carotid stenosis of greater than 50% whilst prior PAD and cerebrovascular disease were shown to be independent and strong predictors of adverse outcome in patients with acute coronary syndromes [7]. The Framingham study indicated that multivascular atherosclerosis reduced the life expectancy of patients: after an initial MI, life expectancy was 13.9 years; after an initial stroke, 8.8 years, and in patients with PAD who later suffered MI or stroke, life expectancy was reduced to 1.5–1.8 years. The prevalence and severity of extracoronary atherosclerosis in 728 patients (572 men and 156 women; average age 59 years) referred for coronary angiography and with a history of coronary disease for at least 2 years were assessed by ultrasonography. This population was divided into three groups: group 1, 115 patients without lesions determined by coronary angiography; group 2, 76 patients with mild coronary stenosis, and group 3, 537 patients with at least one severe coronary artery stenosis (including 294 cases of single vessel disease). The authors observed a strong correlation between the presence, severity and diffusion of CAD and ultrasonographic signs of PAD: the frequency increased from 45% in group 1 to 88% in patients with triple-vessel disease in group 3. About two thirds of patients in group 3 had carotid or lower limb atherosclerosis and half had atherosclerosis or aneurysm of the abdominal aorta. Similarly, simultaneous disease in all three peripheral arterial territories ranged from 12% in group 1 to 51% in group 3. The risk of finding PAD was increased in patients with CAD compared with healthy subjects. In individual peripheral localizations, the risk was 2-fold in cases of mild coronary disease and 3- or 4-fold in patients with triple-vessel disease in whom the risk of finding at least one severe peripheral lesion was increased 10-fold. The authors concluded that the prevalence and severity of ultrasonographic peripheral atherosclerosis in documented coronary patients was closely related to the presence, severity and diffusion of the coronary lesions [8].

Risk Factors for Atherosclerosis

Common major risk factors include age, gender, genetic predisposition, hypertension, hyperlipidaemia, smoking (a significant increase per 10 cigarettes a day), excess alcohol consumption, chronic infection, diabetes
mellitus, an increase by 30 mg/dl in LDL cholesterol, an increase above 15 mg/dl in glucose and elevated fibrinogen levels. A prolonged increase in diastolic blood pressure of 10 mm Hg is associated with a 56 and 37% increase in the incidence of stroke and coronary heart disease (CHD), respectively [9]. The Second National Health and Nutrition Examination Survey Mortality Study (NHANES II) also demonstrated that systolic blood pressure was an important predictor of stroke risk for all groups in the population [10]. It is accepted that diabetes is associated with early onset of atherosclerosis. Almost 75% of type II diabetic patients exhibit CAD. Postprandial blood glucose fluctuation enhances atherosclerotic lesions and exacerbates intravascular thrombogenicity by increased plasminogen activator inhibitor-I synthesis, activation of protein kinase C-β, stimulation of matrix proteins and reduced NO-dependent vasodilatation [11]. More recently studies of obesity and central fat distribution showed a relationship with carotid artery wall thickening in middle-aged women. Physical inactivity and unfavourable dietary and lifestyle patterns are related to cardiovascular disease and premature death. The Atherosclerosis Risk in Communities Study (ARC) suggested a beneficial relationship of physical activity [12]. The Tromso Study revealed sex-dependent protective effects of physical activity in men [13]. The Study of Health in Pomerania (SHIP) demonstrated that physical activity and optimal diet are associated with reduced risk of early carotid atherosclerosis in subjects who never smoked [14]. Serum homocysteine level is a graded risk factor for the incidence of stroke and for the degree of carotid atherosclerosis and also for the incidence of MI; however, the precise relationship with the severity of atherosclerosis in coronary patients is not known. The highest levels of homocysteine were present in patients with both coronary disease and another symptomatic location of atherosclerosis. A small gradient in the extent of coronary atherosclerosis was found with increasing levels of homocysteine. The presence of both hypertension and hyperhomocysteinaemia was associated with more severe coronary atherosclerosis [15]. Further, adverse cardiac events are the consequence of a molecular chain reaction at the site of a vulnerable plaque. Key factors are alterations in platelets and coagulation factors that are activated causing arterial obstruction. Thrombin plays a central role in the development of restenosis and atherosclerosis [16]. Patients with carotid lesions at high risk of thrombo-embolism have more D-dimer than those with normal intima-media thickness (IMT) [17]. D-dimer mean levels are increased in patients with MI, history of stroke and increase gradually in patients with progressing peripheral atherosclerosis.

Liapis and Paraskevas [18] studied the influence of various risk factors on the development of recurrent carotid stenosis after endarterectomy. The cumulative recurrent stenosis rate following carotid endarterectomy was 21.6% at 10 years of follow-up. The presence of CAD was associated with an increased risk of restenosis, while echogenic plaques and hypercholesterolaemia were associated with a lower risk.

**LDL/HDL Levels in the Different Atherosclerotic Diseases**

Plasma lipoprotein concentration is of importance in the development of atherosclerosis [19]. The independent association of high levels of LDL and low levels of HDL cholesterol with coronary atherosclerosis is well established [20]. A longitudinal study of a cohort of 16,209 men over 21 years found serum cholesterol, height and glucose concentration were independently associated with cerebral infarction [21]. Only relatively high cholesterol concentrations are associated with significantly increased risk [22]. There is evidence that elevated cholesterol levels, in association with high blood pressure and smoking, have cumulative effects on carotid stenosis (Framingham heart study with odds ratio 1–10 for moderate carotid stenosis for each 10 mg/dl increase in cholesterol levels). Recent studies found IS was correlated positively with LDL and negatively with HDL cholesterol levels in plasma. Previous research showed a greater elevation in apolipoprotein B (apoB) levels than in LDL cholesterol in CAD. The ARC study in a population of 7,261 men and women free of cardiovascular symptoms evaluated the association between fasting plasma LDL, HDL cholesterol, apoB, apolipoprotein A-I (apoA-I), triglycerides, HDL density subfractions and IMT in extracranial carotid arteries measured using ultrasound imaging. A CAD group was selected for comparison. Lipid factors showed an approximately linear association with carotid thickness: positive for LDL and plasma apoB and negative for HDL and apoA-I levels. Apolipoproteins and HDL density subfractions did not contribute to the association after accounting for LDL and HDL cholesterol. Compared with control subjects, those whose carotid thickness exceeded 0.9 mm had a greater proportional elevation in LDL than in apoB, whereas HDL reductions were small. CAD subjects showed greater elevation of apoB than LDL cholesterol. Although the lipid profiles
associated with asymptomatic carotid wall thickening and stenotic coronary disease are similar, the differences found suggest that LDL is the most important lipid factor in earlier stages of atherogenesis, whereas the metabolism of triglyceride-rich lipoproteins and its effects on LDL and HDL may be more relevant to later atherothrombotic stages. The patients with multivessel disease who did not use lipid-lowering therapy had a 50% increase in the thickness of the carotid intima media (p = 0.030) and a 41% higher oxidized LDL:LDL ratio (p = 0.020) than those with healthy vessels. Furthermore, patients with multivessel disease on statin therapy had a 24% lower oxidized LDL:LDL ratio than those who did not use lipid-lowering drugs (p = 0.027), although the concentration of LDL cholesterol did not differ between the groups. This study supports the hypothesis that lipid oxidation plays a role in the development of atherosclerosis [23].

It has been suggested that immune responses against oxidized LDL activate and regulate the inflammatory processes that accompany all stages of atherosclerosis [24]. Clinical trials have found a beneficial effect associated with a reduction of triglyceride-rich lipoproteins in plasma, leading to a reduction in the progression of coronary atherosclerosis and coronary events [25, 26], but no beneficial influence on carotid atherosclerosis and cerebral events has been demonstrated. Lipid-lowering therapy has a beneficial effect on the incidence of MI and stroke without a major change in plaque size or volume [27].

The difference in pathogenesis underlying the two diseases probably contributes to this, since overlying thrombosis is the major causative factor in MI: IS involves numerous factors, including thrombosis from an atherosclerotic plaque in an extracranial or intracranial vessel, small-vessel disease in the brain and inflammatory arterial disease.

**Is IMT a Predictor of Future Vascular Events in Coronary or Carotid Arteries?**

The IMT of the arterial wall, measured by B-mode ultrasonography in carotid and common femoral arteries, is related to atherosclerosis. Recent studies confirm that two markers of preclinical atherosclerosis, carotid IMT and waist-to-hip ratio were significant and independent predictors of carotid wall thickness [28]. The prevalence and degree of IMT in the carotid arteries have been related to risk factors for cardiovascular disease [29], and the prevalence of symptomatic CHD in cross-sectional studies, and to the risk of development of CHD in cohort studies of symptomatic normal subjects [30]. Held et al. [31] reported data on a subgroup of more than 500 patients with stable angina in which IMT, lumen diameter and the presence of atherothrombotic plaque was assessed in the carotid artery using ultrasound. These assessments were related to the risk of MI or coronary vascular death and the requirement for coronary revascularization during a median follow-up of 3 years. After adjustment for other risk factors, the degree of carotid IMT was only a weak predictor of subsequent coronary events, whereas the presence of carotid plaque was a strong significant predictor in this study.

There is a positive association between carotid artery IMT and the incidence of new MI and stroke in adults 65 years of age or older who did not have a history of cardiovascular disease. Furthermore, risk gradients for MI and cerebral stroke are similar [32]. When statistical adjustment was made for traditional cardiovascular risk factors, carotid artery IMT remained a significant predictor of cardiovascular events. The strength of the associations between IMT and outcome was at least as strong as associations seen with traditional risk factors. Thus, the IMT of the common carotid and the internal carotid arteries is strongly associated with the risk of MI and stroke in asymptomatic older adults. Other arteries, especially medium-sized ones such as the brachial and superficial femoral arteries, do not present so clear a relationship with atherosclerosis progression, suggesting some local differences in pathology.

Mack et al. [33] examined the correlation between changes in both carotid artery IMT and CAD. Measures obtained by carotid ultrasonography and coronary angiography showed a significant correlation, although they each assessed different aspects of the atherosclerosis process. Sen et al. [34] investigated the relationship between aortic and carotid atherosclerosis, and studied the effects of coronary risk factors for these arteries. Significant correlations between maximal aortic wall thickness (MAWT) and aortic wall volume (AWV) with carotid IMT were demonstrated. MAWT, AWV and IMT were significantly higher in patients with CAD compared with controls. MAWT, AWV and IMT had positive correlations with age, systolic blood pressure and triglyceride levels, and a negative correlation with high-density lipoprotein cholesterol. This study demonstrated that both aortic and carotid atherosclerosis was closely correlated with coronary atherosclerosis, and that the atherosclerosis indices are independently associated with age and hyperlipidemia.
Carotid arterial IMT measured by high-resolution B-mode ultrasonography is used as a non-invasive surrogate end point to measure progression of atherosclerosis. However, there are no detailed data on the relationship between aggregation of coronary risk factors and carotid atherogenesis. In the Cholesterol Lowering Atherosclerosis Study, significant correlations between change in common carotid artery IMT and quantitative coronary angiographic measures of change were evident over all coronary artery lesions, and in mild/moderate (<50% diameter stenosis), but not severe (≥50% diameter stenosis) coronary artery lesions. In mild/moderate lesions the correlations with change in common carotid IMT were: the % diameter stenosis, minimum lumen diameter, and vessel edge roughness. While measures obtained by carotid ultrasonography and coronary angiography were correlated, they each assessed different aspects of atherosclerosis [35]. The GENIC case-control study showed that an increased common carotid artery IMT was associated with stroke and may help predict patients at high risk of stroke [36]. Few studies have determined whether carotid artery IMT is associated prospectively with risk of first IS. In the ARC study, carotid IMT, an index of generalized atherosclerosis, was defined as the mean of IMT measured by B-mode ultrasonography at six sites in the carotid arteries. The strength of the association was reduced by the inclusion of putative stroke risk factors, but it remained elevated at higher IMTs. Hence, mean carotid IMT is a non-invasive predictor of future IS incidence [37].

Increased carotid IMT and coronary artery calcification (CAC) are used as markers of early atherosclerosis. In young adults, there is an association between increased carotid IMT and CAC and other cardiovascular risk factors. Carotid IMT in addition to CAC may provide a means to identify young adults with premature atherosclerosis. Few studies were population-based and furthermore little attention has been given to the influence of CHD risk factors on IMT in populations at low risk for CHD. Authors found thinner IMT than those in high-risk populations, suggesting that an increased IMT might reflect local atherosclerosis [38]. Protective factors such as HDL cholesterol or regular and moderate alcohol consumption are probably important determinants of the early stages of atherosclerosis in these low-risk populations [39].

Other risk factors displaying statistically significant correlations with mean carotid IMT were tissue polypeptide antigen level and activity, plasminogen activator inhibitor-1 antigen level and level of HDL cholesterol. The significant association between carotid IMT and CHD suggests that carotid and coronary atherosclerosis evolve simultaneously. Hence carotid IMT can be used as a predictor of coronary atherosclerosis.

### Atherosclerotic Plaque Pathology

What is uncertain is whether atherosclerotic plaques are diverse in their structural, cellular and molecular characteristics. Recent studies suggest that carotid artery atherosclerosis is a symmetrical disease, particularly in the degree of calcification [40] and inflammation [41]. However, this symmetry in patients undergoing endarterectomy with advanced disease is not so clear, suggesting that local anatomy, flow conditions and risk factors may determine unilateral plaque progression.

### Appearance and Structure of Coronary Plaques

Stable angina is associated with smooth, fibrous coronary artery plaques, whereas unstable angina, acute MI and sudden cardiac death are invariably associated with irregular or ruptured plaques [42]. Evidence from a prospective angiographic study suggested that severe stenoses progressed to total occlusion about 3 times more frequently than less severe lesions, but this process infrequently resulted in MI [43]. In contrast, most of the severe carotid stenoses led to cerebral infarction. These findings support the hypothesis that disruption of small plaques is important in the pathogenesis of acute MI, whereas longstanding severe stenosis more commonly results in total vessel occlusion with a small or silent infarction, perhaps because of the presence of well-developed collateral vessels. In the coronary arteries, small plaques tend to be lipid-rich and prone to disruption. Markedly stenotic plaques tend to be fibrotic and stable [44]. The most important contributors to coronary plaque disruption are morphology, lipid composition, presence of foam cells and stresses across the vessel wall [45]. Foam cells can secrete large amounts of procoagulant tissue factor (TF) [46] that stimulate thrombus formation in contact with blood [47]. Atherosclerotic plaque rupture with atheromatous debris; distal embolization is dependent on plaque composition rather than plaque burden. Features of vulnerability are: a large lipid core, a thin fibrous cap and an inflammatory filtrate rich in monocytes and macrophages [48]. Studies of ruptured plaques indicate that
large necrotic cores, a fibrous cap of less than 65 μm in thickness, intraplaque haemorrhage and infiltrating macrophages within the cap are indicators of instability [49–51].

**Events Leading to Coronary Plaque Rupture**

The cellular events leading to plaque rupture are not fully understood. Recruitment of T lymphocytes within the atheroma was increased at the site of future rupture. T lymphocytes are the source of interferon-γ that markedly decreased the ability of human smooth muscle cells to express interstitial collagen genes [52]. This provides a mechanism to explain impaired maintenance and repair of the collagenous meshwork in vulnerable plaques, rendering it weak and prone to rupture. In addition, accelerated degradation of collagen and other matrix components may contribute to weakening of the fibrous cap. Increased activity of matrix metalloproteinases (MMPs) has been demonstrated during atherosclerotic plaque disruption [53]. MMPs may modify the extracellular matrix and promote stabilization by promotion of smooth muscle cell mitogenesis, or alternatively, destabilize vulnerable plaques by promoting matrix destruction, angiogenesis, leucocyte infiltration and apoptosis [54, 55]. Although these mechanisms probably play a prominent role in plaque rupture, other factors may also contribute to the unstable coronary syndrome. There is impaired responsiveness to endothelium-dependent vasodilators in diseased portions of human coronary arteries [56] that may contribute to impaired flow in these vessels, particularly at sites of underlying stenoses. The precipitating event in most cases of acute MI involves thrombotic occlusion of the vessel, usually at sites of plaque disruption.

**Appearance and Structure of Carotid Plaques and Factors Associated with Rupture and Thrombosis**

Endothelial dysfunction and changes in arterial wall morphology including thickening of the tunica intima, excess synthesis of the collagenous matrix (fibroblastic intimal thickening) and permanent or dynamic deposition of lipids (fatty streaks) occur in childhood. Definite atherosclerotic plaques in the carotid arteries are usually not evident before the menopause in women or the age of 40 years in men. Long-term exposure of the vessel wall to risk factors is required to overcome the highly effective defence mechanisms that are not yet fully understood. Because of vascular remodelling, lumen obstruction is compensated for by widening of the vessel. For stenosis to develop, plaques must evolve into complicated lesions characterized by small ruptures and consecutive mural thrombotic episodes. This process commonly starts with small- to medium-sized plaques. Potential determinants of plaque rupture are the composition of the lesion (large lipid-rich core), damage to the fibrous cap and haemodynamic stress. Based on pathological studies, plaque fissuring is a frequent event, while the formation of overlying large thrombi (with progression of stenosis or vessel occlusion) is rare (fig. 1). These data emphasize the significance of local and systematic thrombus-promoting factors. The risk profile of advanced atherogenesis includes markers of enhanced prothrombotic capacity, attenuated fibrinolysis and clinical conditions associated with defective coagulation. Almost all patients with more than three procoagulant risk conditions had carotid stenosis or showed progression of pre-existing stenosis during a 5-year period [57]. Indeed, diabetic patients with unstable carotid disease measured by the presence of symptomatic carotid disease, plaque echogenicity on ultrasound, or plaque vulnerability as evidenced by ulceration on histology have significantly higher levels of markers of haemostasis, fibrinolysis and plaque remodelling [58]. In a recent study, 63.1% of patients had carotid plaque progression and the combined 5-year adjusted risk of stroke, MI and vascular-associated death was 15.7% [59].

Atherosclerotic plaque irregularity and rupture of the carotid artery are closely associated with the occurrence of cerebral ischaemic events [60]. Patients with irregular or ulcerated plaques determined by carotid angiography have a higher risk of IS irrespective of the degree of stenosis of the vessel lumen [61]. The incidence of vessel-to-vessel embolism from the carotid territory is about 5.2% in both extracranial carotid artery stenosis and middle cerebral artery stenosis [62]. Furthermore, systemic factors, such as infection, autoimmune disease, or genetic predisposition might be partly responsible for plaque instability and rupture [63].

If plaque stability is modulated by systemic factors, then plaque morphology at one site might predict plaque morphology at a distant site. A study of carotid bifurcation angiograms from patients with a recent symptomatic carotid stenosis determined the extent to which plaque surface irregularity and ulceration at one site (the symptomatic carotid artery) was associated with irregularity and ulceration at a distant site (the contralateral carotid artery) and the extent to which plaque morphol-
ogy at these sites was associated with previous MI and subsequent non-stroke vascular death (due mainly to CAD) \[64\]. Furthermore, patients with plaque surface irregularity or ulceration in the symptomatic carotid artery were twice as likely as those with a smooth plaque to have irregular or ulcerated plaque in the contralateral carotid artery. Patients with irregular or ulcerated plaques in one or both carotid arteries were more likely to have had a previous MI than patients with smooth plaques and were more likely to suffer a non-stroke vascular death on follow-up. These findings suggest that some individuals have a systemic predisposition to plaque growth, irregularity and rupture that is independent of recognized vascular risk factors.

Increased lymphocyte concentration, macrophage accumulation, dysregulated nitric oxide metabolism, tumour necrosis factor-α, MMPs, adhesion molecules, phospholipases, autoimmunity, multiple infections, proliferating smooth muscle cells, intraplaque haemorrhage, extensive vascularization of the plaque and apoptosis may contribute to symptomatic carotid disease (fig. 2). However, it is uncertain what link exists between cytokines produced during plaque formation, circulating soluble cytokines in serum and their concentration in the areas of surviving cerebral penumbra.

Studies of carotid plaques have demonstrated the presence of significant numbers of inflammatory lymphocytes, and autoimmunity may be involved during atherogenesis. Irvine et al. \[65\] demonstrated that plaques with >70% stenosis from asymptomatic and symptomatic patients had higher expression of platelet-derived growth factor and receptors and more macrophages and intraplaque haemorrhage than plaques with <70% stenosis.

**Relationship between Plaque Constituents and Occurrence of Symptomatic Disease**

Controversy exists as to the relationship between plaque composition and the development of neurological symptoms. Studies of a long series of patients with carotid stenosis showed that the extent of stenosis was not correlated with symptoms and was unaffected by the morphology of the plaque \[66\]. This, however, suggests that plaque morphology may independently have a role.
In the presentation of carotid disease. Intraplaque haemorrhage, lipid levels and necrosis seem to be more common in plaques causing high-grade symptomatic stenosis [67, 68]. A significant correlation between plaques containing amorphous material mixed with cholesterol and neurological symptoms was reported by Feeley et al. [69]. Interestingly, the amount of fibrous tissue found in asymptomatic patients was higher than in patients experiencing increasing numbers of ischaemic events. Other plaque features like foam cell infiltration in the fibrous cap, thinning or rupture of the cap, lipid-rich cores beneath the cap, cholesterol crystals and necrosis are associated with progression of atherosclerotic disease and neurological symptoms [70]. Leen et al. [71] found that an eosinophilic amorphous material mixed with cholesterol was the predominant nonfibrous component in symptomatic plaques. However, in an earlier study of Golledge et al. [72], carotid plaque morphology, plaque surface features as well as visualization by echolucency of the plaque did not distinguish between patients who presented with stroke without warning and symptomatic patients exhibiting TIA, amaurosis fugax, crescendo TIA, stroke with warning). Liapis et al. [73] studied the impact of the carotid plaque type on recurrent carotid stenosis, future cardiovascular events and patient survival. Hypertension, CAD, and echolucent plaques were associated with a higher incidence of cardiovascular events. Patients undergoing endarterectomy for symptomatic disease with ulcerated complicated carotid plaques had higher intraplaque D-dimer levels. Furthermore, hypercholesterolemic patients with ulcerated complicated plaques had significantly higher fibrin turnover indicating greater plaque procoagulant activity and risk for symptomatic disease [74]. Markers of plaque remodelling may be related with the occurrence of symptomatic disease. In situ zymography established that unstable carotid plaques (estimated by clinical and morphological methods) had higher MMP activity. This suggests that MMPs definitively contribute to plaque remodelling and possibly contribute to symptomatic carotid disease. Further, patients with prior history of CAD had higher MMPs activity independently of any other risk factor. This suggests that remodelling

**Fig. 2.** a Advanced carotid lesion, type V, taken from 67-year-old diabetic patient without history of cardiovascular disease who died of septic shock. ×40. Carotid lesions as compared to coronary are usually more heterogeneous, with less lumen stenosis, with important calcification (arrow), prominent lipidic core early surface asymptomatic rupture and intraplaque hemorrhage. Angiogenesis is also abundant in the various areas of the plaque showing newly formed blood vessels. New vessels are formed close to inflammatory areas (inset b), as well as in the areas with a very limited number of inflammatory cells (inset c). b, c ×200; immunostaining with antibody against CD105; 1:100; Endoglin, R&D Systems.
properties of MMPs may be similar in both coronary and carotid diseases. Interestingly, patients with asymptomatic carotid disease, but with plaque progression within the last year prior to endarterectomy had higher intraplaque MMP-8 activity than patients without progression. Patients with hypertension had higher intraplaque MMP-8 activity, further linking this MMP with the most frequent risk factor in patients with symptomatic carotid disease [75].

**Plaque Rupture: a Comparison of Coronary versus Carotid**

Rupture-prone high-risk coronary plaques, in particular, are thought to consist of a thin fibrous cap covering an atheromatous lipid-rich core containing cholesterol and its esters [76]. Recent studies have suggested that plaque morphology and biomechanical stresses should be considered. In vivo magnetic resonance imaging can be used to predict stress within plaques and showed greater stress in symptomatic than asymptomatic patients, with an increased rupture risk [77]. Indicators of plaque rupture may be intrinsic stresses (i.e. the continued accumulation of lipoproteins from plasma with or without uptake by macrophages to form foam cells) or extrinsic flow-dependent stresses. Leen et al. [71] concluded that cholesterol deposition precedes intraplaque haemorrhage rather than the reverse, indicating that haemorrhage is an effect rather than a cause or pathogenic factor. Gronholdt et al. [68] showed that the extent of haemorrhage in a plaque was positively associated with lipid concentration and negatively associated with fibrous tissue content. An alternative pathogenesis to plaque rupture/intraplaque haemorrhage is bleeding into plaques from thin-walled new vessels originating from the vasa vasorum and commonly found at the plaque base [79]. This bleeding may theoretically increase intraplaque pressure, with resultant cap rupture from the inside.

Intrinsic stresses also include chronic inflammation with degradation of the extracellular matrix weakening the fibrous cap. The cells involved in inflammation are activated macrophages and/or mast cells that by phagocytosis or secretion of proteolytic enzymes [80] degrade collagen, destabilizing the fibrous cap. Smooth muscle cells, on the contrary, stabilize the plaque by secreting collagen [81]. Plaque rupture may lead to intraplaque haemorrhage, formation of superimposed thrombosis, embolism, and subsequent neurological symptoms.

In contrast, carotid plaques seem to undergo slow rupture over many years and often remain asymptomatic. However, local ulceration increases the risk of focal microthrombi formation and subsequent thrombosis with silent infarction or slow formation of distal and later occlusive thrombi. Carotid plaques appear by histology to be more advanced and present a more mixed pathology. Even in plaques at sites where erosion predominates, focal ulceration occurs with surface thrombi formation. This probably explains why carotid plaque rupture is not as acute a clinical syndrome as is the case of coronary plaques.

**Thrombus Formation Precedes Acute Cardiovascular/Cerebrovascular Events**

Thrombus formation plays a fundamental part in the development of acute coronary syndromes. Angiographic, pathological, and biochemical data implicate the formation of a thrombus overlying a rupture in the lining of the plaque in the pathogenesis of unstable angina. Subclinical episodes of plaque disruption with local thrombin activation and subsequent healing may represent a major pathway for progression of atherosclerotic lesions. Pathological studies have shown repeatedly in humans and in experimental animals that growth of an atherosclerotic plaque occurs by outward, abluminal expansion [82]. This phase of growth may last for years, and only after the plaque burden occupies half of the luminal area does the plaque protrude into the lumen, becoming visible by angiography and capable of impairing blood flow. This suggests that angiography visualizes the lumen rather than the plaque itself and may underestimate plaque size.

In transmural MI occlusive thrombi develop in a protracted and recurring manner, which is reflected in their layered appearance [83]. Based on autopsy studies, 85% of occlusive thrombi are rich in fibrin and erythrocytes and the remaining 15% are pure platelet thrombi containing little or no fibrin [84]. The phenomenon of distal appositioning beyond the site of plaque rupture was found in 50% of cases of fatal infarction, whilst proximal apposition was seen in 25% of cases. Thrombus formation and platelet deposition is 6 times higher on the lipid-rich core than on other arterial wall components [85]. The nature of the plaque component exposed by rupture determines the degree of its activation, i.e. external coagulation pathway, thrombin activation, fibrin deposition and platelet activation [86]. TF is a key molecule in
the coagulation and previous studies have demonstrated that increased expression of TF in high-grade carotid stenosis is associated with plaque destabilization, clinically evidenced by both a history of previous ischaemic symptoms and the detection of micro-emboli in long-term transcranial Doppler ultrasonography monitoring of the ipsilateral middle cerebral artery [87]. Further, active carotid plaques (rich in inflammatory cells) were found to express abundantly TF. Blood-borne TF activity prior to endarterectomy predicts cerebrovascular and peripheral vascular disease events at 1 year in elderly patients subjected to endarterectomy for high-grade carotid stenosis [88].

**Plaque Calcification**

The precise process of calcification in plaques is still unclear. Coronary plaque calcification accounts for only 5% of acute coronary syndromes [89]. Calcification increases in plaques with age and the overall plaque burden, but not with the degree of stenosis in coronary arteries [90]. Calcium seems to stabilize the plaque, preventing disruption and thrombosis. Calcium is found less frequently in lesions responsible for unstable angina and MI [91]. CAC reflects the extent of coronary artery arteriosclerosis but the extent of CAC is not well described in older adults. Overall, CAC scores were increased in subjects with clinical cardiovascular disease or evidence of subclinical cardiovascular disease rather than those with no evidence of disease. Older adults with evidence of clinical or subclinical CAD had higher total CAC scores. Though the extent of CAC was lower in those with minimal evidence of CAD, the range was broad and not explained by CAD risk factors.

There is uncertainty over carotid artery calcification and the risk of neurological events. The presence of calcification is a frequent event in carotid plaques, especially those with mixed histology. In recent studies 13% of patients presented lamellar bone formation, which was correlated directly with the presence of sheet-like calcifications. Bone formation occurred in heavily calcified carotid lesions devoid of ulceration and haemorrhage, and patients with extensive calcification of the carotid plaques were less likely to have symptomatic disease [92]. Determination of the extent of calcified carotid plaques may be useful to improve the predictive value of risk factor-based multivariate models. In one study calcified plaques of carotid arteries were significantly correlated with coronary artery stenosis, hypercholesterolaemia, increasing age, diabetes, hypertension, and left ventricular hypertrophy in contrast to smoking status, body mass index and male sex [93].

**Extrinsic Factors, Shear Stress and Haemodynamics**

Extrinsic stresses on a plaque are haemodynamic forces (i.e. shear stress, a sudden increase in blood flow, blood pressure, and pulse rate) acting on the weak shoulders of the cap. In particular, mechanical stresses of flowing blood on the vessel wall are important stimuli that influence atherogenesis by regulating endothelial function, smooth muscle cell behaviour, and the interactions of endothelium with other circulating components [57]. The carotid plaque is typically situated in the bifurcation of the artery, where a mismatch in flow impedance, abnormal wall tension, and non-laminar turbulent flow may predispose to further atherogenesis and eventually to plaque rupture. Superimposed thrombosis can also grow on an intact plaque if hyperthrombogenicity exists because of platelet activation, hypercoagulability, and/or impaired fibrinolysis [95]. Pulsatile blood flow through coronary arteries is an important regulator of the structure and function of these vessels, and is implicated in the pathogenesis of atherothrombosis. In the large epicardial coronary arteries, atherothrombosis localizes to the outer wall of one or both daughter vessels at major bifurcations. However, in the coronary vasculature, flexing of the vessels because of cardiac contractions introduces a complication. Even more problematic are the effects of curvature of these vessels as they cross the surface of the heart, as curvature can introduce substantial effects on shear. In the coronary arteries, flow-induced alterations can also affect the development of collateral supply. In consequence, haemodynamics leads to pathological arterial remodelling and may significantly affect progression of both coronary and carotid diseases.

**The Importance of Plaque Stability**

The morphological stability of carotid arterial plaques correlated significantly with coronary artery stenosis. Morphologically unstable plaques of the carotid artery were able to predict unstable forms of coronary obstruction with a sensitivity of 68%, specificity of 85%, predictive power of 72% and a likelihood ratio of 4.5 [94].
Inflammation and Atherosclerosis

Chronic or recurrent infections, particularly with *Chlamydia pneumoniae*, *Cytomegalovirus*, *Helicobacter pylori* and periodontal infections have been observed in patients with atherothrombosis in the cardiac, cerebral and lower extremity circulations [96]. CD4+ T cells reactive with *Chlamydia* proteins have been cloned from human lesions, and CD8+ T cells also present, recognize viral antigens and may result in death of arterial cells and acceleration of atherosclerosis [97]. Peptidoglycan, a major component of the wall of gram-positive bacteria, abundantly present in all human mucosa has been observed in atherosclerotic arteries in association with the vulnerable plaque phenotype. Peptidoglycan binds to CD14 on macrophages and induces pro-inflammatory cytokine and metalloproteinase synthesis [98]. Human atheromatous plaques taken from aorta, coronary, and carotid arteries contained dendritic cells, which may mediate autoimmune responses during plaque evolution. These atheromas were positive for DC-SIGN antigens, which mediate adhesion to T lymphocytes and endocytosis [99]. Lipid-rich atherosclerotic plaques have elevated activity of pro-inflammatory enzymes, which contribute to plaque rupture. Elevated levels of pregnancy-associated plasma protein (PARP-A), a metalloproteinase, have been found in hyperlipidaemic patients at high risk of cardiovascular events and with echogenic, unstable carotid plaques [100].

The possible mechanism leading to symptomatic vascular disease may be explained by increased coagulation [101], endothelial dysfunction [102], plaque instability [103, 104], and increased progression of the plaque due to inflammation [105]. The American Physician's Health Study showed that baseline levels of C-reactive protein (CRP) were significantly higher among subjects who later had an MI or IS than among those who remained free of vascular disease [106–108]. CRP, an acute phase reactant, added important prognostic information to patients suffering from metabolic syndrome in respect of MI, stroke, coronary revascularization and cardiovascular death [109]. A recent study has shown that CRP was a stronger predictor of cardiovascular events than was LDL cholesterol levels [110]. This is important, as in many situations atherosclerosis occurs in the absence of hyperlipidaemia. Increased levels of CRP are associated with a worse outcome in patients with IS, independently of other prognostic factors like fibrinogen [111]. CRP is an effector molecule able to induce and promote atherothrombosis. Endogenous expression of CRP is increased in atherothrombosis and Plaque Heterology
A common variant in the promoter of the human stromelysin gene, causing reduced enzyme expression, has been associated with the progression of coronary atherosclerosis. On the other hand, increased stromelysin activity may promote plaque rupture. The results demonstrate that polymorphisms in the promoter region of stromelysin are associated with structural and functional characteristics of the common carotid artery in healthy male subjects without major risk factors for atherosclerosis. Individuals with the 6A/6A genotype (associated with lower enzyme activity) show a triad of events, namely increased wall thickness, enlarged arterial lumen, and local reduction of wall shear stress, which might predispose them to atherosclerotic plaque localization [120].

Another genetic predisposing factor is the human serum paraoxonase (PON1) gene. It exists in two polymorphic forms differing in amino acids at positions 192 (glutamine and arginine, Q and R, respectively) and 55 (methionine and leucine, M and L, respectively). PON1 protects LDL from oxidation, and if PON1 is inactivated LDL oxidation is increased. Authors compared PON1 isoforms, Q and R, for the extent of lipid peroxidation in human coronary and carotid lesions. They concluded that PON1 may be anti-atherogenic because it hydrolyzes lipid peroxides in human atherosclerotic lesions [121]. The San Antonio Family Heart Study used carotid artery plaque as a genetic marker of subclinical atherosclerosis. They established that that focal carotid artery plaque is heritable after discounting established cardiovascular risk factors [122].

Human carotid plaques, coronary arteries, aorta and in-stent stenosis specimens were examined for differential gene expression in vascular smooth muscle cells (VSMCs) [123]. Sequencing of difference products identified several genes, the expression of which was increased in primary plaque VSMCs, including IGF-BP2, cartilage link protein, enteric muscle γ-actin, α-tropomyosin and laminin-β1. Genes associated with cell proliferation, contraction and cell/matrix signalling were increased in in-stent stenosis versus normal medial VSMCs. Numerous studies pointed at the possible genetic predisposition to have coronary and carotid atherosclerosis. Some candidate genes related to risk of coronary disease or stroke have been already selected. Future studies based on wide-genome association analysis will bring new data.

**Gene Expression Analysis of Cardiovascular Disease**

Although it is accepted that genetics contributes to the development of cardiovascular disease, identification of the specific genes involved has been difficult. CAD is a multifactorial disease influenced by both genetic and environmental factors and their interactions [124]. Previously the identification of specific causative genes was a laborious process involving Northern and Western blotting and immunohistochemistry and studying either a single gene or transcript or a maximum 5–50 genes at a time. Identification of the global gene changes and their variants in CAD may allow the development of individual therapies [125, 126]. Microarray analysis is a powerful technique that allows the simultaneous screening of multiple gene transcripts, either the whole genome, using a gene chip, or sections associated with a particular aspect of a disease process [127].

Satterthwaite et al. [128] studied gene expression in CAD and found 361 genes differentially expressed compared to normal artery. These included inflammation-associated interleukin-1β and interleukin-8 and signal transducer and activator of transcription, IL-6. A much larger study of 12,000 genes in severely atherosclerotic coronary arteries [129] showed upregulation of 55 genes, of which 49 were novel and included genes associated with inflammation (tumour necrosis factor-α-induced protein-2), apoptosis (PIM-2 oncogene) and cell migration (VCAM-1). They also found one gene coding for a reducing agent (GST) downregulated. Other studies have tried to identify gene expression in symptomatic and asymptomatic carotid plaques from the same patient and showed that the former overexpressed two genes, CD163 and HO-1 associated with iron-heme homeostasis [130]. Gene profiling has shown that apoptotic genes play a central role in carotid plaque development. For example Martinet et al. [131] found 205 of these genes upregulated and death-associated protein kinase located in foam cells where it contributed to the uptake of LDL.

An alternative approach is to use protein arrays to study changes in protein composition of plaques. Since this is a newer technique, currently there are relatively few studies. Slevin et al. [132] found proteins associated with apoptosis (caspase-9), DNA repair mechanisms (topoisomerase-IIα) and cell signalling molecules expressed in carotid plaques. Vaisar et al. [133] used shotgun proteomics to show that proteins involved in the metabolism of HDL were associated with CAD. Proteomics has the potential to reveal novel important mediators in-
involved in the development of unstable atherosclerosis and phosphoprotein arrays will help identify activation of signal transduction cascades.

It appears that rapid advances in genomic tools and techniques (Human Genome Project, International Hap-Map Project, high-throughput genotyping, among others) will transform our understanding of cardiovascular medicine. Wide-genome association studies are currently being carried out and a number of candidate genes are being identified. However, results have to be taken with caution before they are reproduced in different populations. Further studies will involve detailed comparisons of gene and protein expression in specific plaque regions from coronary and carotid arteries at different stages of development. By identifying genes and pathways involved in progression towards instability, these techniques will help to transform treatment [134].

Conclusions

Large population-based studies, like the Framingham Study, clearly demonstrated the co-existence between coronary and carotid artery disease. The severity of atherosclerosis in one vascular bed was related to the severity in the other peripheral arteries. Both entities shared similar risk factors. Further, the IMT of the common carotid and the internal carotid arteries or the presence of atherosclerotic plaque was strongly associated with the risk of MI and stroke. This suggests that coronary and carotid atherosclerosis evolve simultaneously. In respect to symptomatic coronary or carotid artery disease some clear variances exist. Disruption of small lesions and local formation of large occluding thrombus are important in the pathogenesis of acute MI. In contrast, in the carotid territory low to moderate stenosis remains usually clinically asymptomatic and large plaques generally have only small intramural thrombi. However, microemboli may form at the surface of the ulcerated carotid plaque and lead to cerebral strokes or asymptomatic silent infarcts. On anatomopathology, large coronary plaques tend to be fibrotic and stable, while carotids with severe stenosis usually are unstable with ulceration, intraplaque hemorrhage, important inflammation and big lipidic core. Carotid artery plaques appear at a much higher age, suggesting that defence mechanisms protecting carotids are much better developed than in the case of coronary arteries. Individual responses to shear stress may partially explain differences between coronary and carotid atherosclerosis. Variability in the plaque composition between coronary and carotid arteries exists and marks differences in the pathophysiology of both diseases. Plaque heterogenous cellular population contributes independently to single vascular events and changes throughout the life of the coronary and carotid artery. These cellular and molecular hallmarks are the main cause of the difference between two territories, atherosclerotic plaque progression and resistance to common risk factors. The remodelling properties of both territories are possibly driven by different plaque composition at different stages of disease evolution. The adequate understanding of dynamic pathophysiology of both diseases may offer numerous approaches to treat patients in the future. This concept will be supported by current studies, especially those of wide-genome association analysis of coronary and carotid disease patients. It is expected that new target genes and molecules will be identified in the near future.
