Abstract

Background: Management of tunneled, cuffed, central venous catheters in hemodialysis (HD) patients with bacteremia remains a challenge. Attempts to salvage the catheter with systemic antibiotics alone have been associated with increased risk of metastatic infectious complications. Methods: Retrospective case series of patients with infectious complications in a chronic dialysis unit, affiliated with a tertiary care university hospital. Results: Between 1996 and 1999, when we treated HD catheter-associated bacteremia with systemic antibiotics alone, we encountered a clustering of 8 cases of paraspinal/vertebral infections in a population of 162 patients. After changing our protocol, i.e., routine catheter exchange over a guide wire at 48 h, while on systemic antibiotic therapy, we did not encounter any new cases of paraspinal/vertebral infections over a 15-month period. Conclusion: Our experience suggests that routine exchange of tunneled, cuffed catheters over a guide wire in HD patients presenting with bacteremia may significantly reduce serious infectious complications, e.g., epidural abscess/vertebral osteomyelitis.

Introduction

The maintenance of vascular access is a major problem in the management of patients on chronic hemodialysis (HD). Permanent or semi-permanent catheters for vascular access are utilized in 10–30% of patients with end-stage renal disease requiring HD [1]. Well-recognized catheter-related complications include bacteremia, exit-site or tunnel infections, and frequent clotting episodes requiring intervention. Infections account for up to 40% of these complications [2].

Management of infected HD catheters is difficult and there are few evidence-based guidelines in that regard. Several studies have shown successful treatment of catheter-associated infection without catheter removal [3–5]. However, persistent bacteremia and metastatic complications such as epidural abscess, osteomyelitis, discitis and endocarditis remain a major problem in these patients [6, 7]. Current DOQI guidelines (guideline 26) recommend treatment with parenteral antibiotics and removal of the catheter only if the patient remains symptomatic [8]. Although one report has advocated routine catheter exchange over a guide wire at 24–48 h [9], it has not been adopted as standard of care by most dialysis units, and currently there is no consensus among the nephrologists on the proper management of catheter-associated bacteremias. A 2- to 3-week course of appropriate systemic antibiotic therapy, without catheter removal, has resulted in...
catheter salvage in only 20–30% of these patients [4, 5]. This may be due to the fact that systemically administered antibiotics have insufficient penetration into the lumen of the HD catheter [10], and thus may not kill bacteria in the biofilm within the catheter lumen [11, 12], hence the rationale for routine exchange of the infected catheter over a guide wire [9] or the use of the ‘antibiotic-lock technique’ [13, 14].

Paraspinal/vertebral infections are relatively rare but catastrophic complications of dialysis catheter infection that require surgical treatment and often leave the affected patients paraplegic or dead. These complications often follow a bacteremic episode and are associated with extended, repeated attempts at salvage of the infected catheters [6, 15]. The time between diagnosis of bacteremia and paraspinal/vertebral infection remains uncertain.

Between 1996 and 1999 we encountered a clustering of 8 cases of paraspinal/vertebral infections among our chronic HD patients. Seven of these patients had documented bacteremia that preceded the diagnosis of paraspinal/vertebral infection by 1–20 weeks. Based on our past protocol, the catheter-associated bacteremias were managed with appropriate systemic antimicrobial agents and the catheter was not removed in patients who had good clinical and bacteriologic response. However, after encountering the cluster of paraspinal/vertebral infections we changed our practice of attempted catheter salvage with systemic antibiotics alone, i.e., we routinely exchanged the tunneled catheters over a guide wire at ~48 h, in addition to parenteral antibiotics. When there was evidence of tunnel infection, a new tunnel was created and the replacement catheter was placed at the new site. In retrospect, we did not encounter any new cases of paraspinal/vertebral infections over the subsequent 15 months in which we adopted the new protocol.

**New Catheter Exchange Protocol**

In hemodynamically unstable patients the catheter was discontinued immediately and HD was provided via intermittent temporary catheters until their blood cultures were consistently sterile. If the patient was clinically stable, the cuffed catheter was exchanged over a guide wire within ~48 h of presentation with bacteremia, provided there was no evidence of tunnel infection. If there was exit site infection, or erythema or tenderness over the subcutaneous tunnel suggestive of tunnel infection, a new tunnel was created and the replacement catheter was placed at the new site.

In a retrospective review of our experience, after changing our clinical practice we found no new cases of paraspinal/vertebral infections over a 15-month period.

**Technique of Catheter Replacement**

Under ultrasound guidance the vein was punctured and a guide wire was introduced into the central vein. The puncture site was extended into an about 1-cm skin incision and the subcutaneous tissue was infiltrated with 1% Lidocaine solution to an exit site in the chest or the thigh area, depending on the site of insertion. The exit site was created with a scalpel and the cuffed catheter was pulled through the subcutaneous tunnel from the skin incision. The venous puncture site was extended and dilated up to 16 French over a guide wire. A 16-French peel-away sheath was introduced into the vena cava and the catheter was inserted through the peel-away sheath. The optimal catheter position and free flow aspiration and injection in both ports were confirmed under fluoroscopy. The catheter ports were filled with 1:1,000 dilution heparin solution. A 3.0 nylon suture was used for skin closure and to secure the catheter.

If the catheter was exchanged over a guide wire, a skin incision was made close to the venous entry point of the catheter. After exposing the catheter it was pulled back a few centimeters and divided. Hemostasis was established by clamping the proximal portion of the catheter in the vein. A guide wire was passed through the old catheter and the catheter was pulled out while direct pressure was applied over the vein. Using the same tunnel a new catheter was pulled through the tunnel into the vein through the peel-away sheath, as described above.

**Results**

The clinical features of the 8 patients with paraspinal/vertebral infections were as follows: mean (± SD) age at presentation was 62.5 ± 10.5 years; 7 patients were male; 5 had diabetes mellitus; 6 patients used a double-lumen, tunneled, cuffed catheter for HD, and 2 patients received HD treatments via synthetic arteriovenous (AV) grafts.

The presentation of paraspinal/vertebral infection in all cases was back pain localized to cervical (1 case) and/or lumbar region (8 cases). Two patients presented with neurologic deficits suggestive of spinal cord compression. Six patients had fever at presentation. Leukocytosis (WBC ≥ 10,000/mm³) was present in 5 patients.

The time course of bacteremia, antibiotic administration, removal of the vascular access, and the diagnosis of
paraspinal/vertebral infections are shown in figure 1. All patients had documented bacteremia that preceded the diagnosis of paraspinal/vertebral infection by 1–20 weeks. Immediately prior to this, 4 patients had sterile blood cultures diagnosed.

The microorganisms identified were vancomycin-resistant enterococcus (n = 1) and *Staphylococcus aureus* species (n = 7) – coagulase-negative (n = 4), methicillin-sensitive (n = 2), and methicillin-resistant (n = 1).

The diagnosis of paraspinal/vertebral infections was made by magnetic resonance imaging (MRI) in all of the 8 patients. The infections included epidural abscess, vertebral osteomyelitis and discitis. Needle aspiration biopsy was performed in 6 of the 8 patients to confirm diagnosis. Figures 2–4 illustrate some representative MRI findings in 3 patients.

Therapy was instituted with intravenous antibiotics according to the bacteriologic sensitivities and was continued for 4–6 weeks in 7 patients, and for 12 weeks in 1 patient. Surgical debridement was performed in 4 patients. Therapy was considered successful by sterilization of the blood and the absence of recurrent bacteremia.

Over the subsequent 15-month period in which we changed our protocol, i.e., replacing the catheters at
~48 h in addition to the systemic antimicrobial therapy, we encountered no new cases of paraspinal/vertebral infections in our HD patients with tunneled, cuffed catheters.

During both time periods when HD catheter-associated bacteremia was suspected based on clinical signs and symptoms of fever and chills, blood cultures and sensitivities were sent, and the patients were empirically treated with vancomycin and gentamycin until blood culture results became available, at which time, the choice of antibiotic was tailored according to the antimicrobial sensitivity of the microorganism identified.

**Fig. 2.** MRI of the lumbosacral spine with gadolinium contrast. An anterior epidural abscess (arrow) is seen at the L3–L5 level, significantly effacing the cal sac. Biopsy revealed acute inflammation, and culture grew vancomycin-resistant *Enterococcus faecium*.

**Fig. 3.** MRI of the lumbosacral spine with (a) and without (b) gadolinium contrast showing discitis (arrow head) and osteomyelitis (arrow) at the L5–S1 level. Biopsy revealed acute and chronic inflammation with necrosis, and culture grew *Staphylococcus aureus*. 

Routine Replacement of HD Catheter
Fig. 4. MRI of the lumbosacral spine without gadolinium contrast. a A T1-weighted image. b A T2-weighted image. Osteomyelitis (arrow) and discitis (arrow head) involving L2 and L3 are present. Biopsy revealed acute inflammation, and culture grew coagulase-negative Staphylococcus aureus.

In the former part of the study (1996–1999), systemic antibiotic therapy was continued for ~3 weeks in an attempt to sterilize the catheter. In the latter part of the study, the systemic antibiotics were discontinued 2–3 weeks after the catheter had been exchanged over a guide wire.

During the 20 months prior to the change in our protocol, we documented 38 bacteremic episodes in our HD population, of which 86.5% were with gram-positive microorganisms (S. aureus 25%, coagulase-negative staphylococcus 65%, enterococci 10%), 11% with gram-negative microorganisms, and 2.5% with yeast infection. During the 15 months after the change in our protocol, we documented 34 bacteremic episodes, of which 82% were with gram-positive microorganisms (S. aureus 31.5%, coagulase-negative staphylococcus 52.5%, enterococci 16%), 14% with gram-negative microorganisms, and 4% with yeast infection. Thus, the incidence of bacteremia and their microbiology were very similar in the two time periods. Moreover, we found a similar duration of hospitalization for documented bacteremic episodes in each time period (mean ± SD, 5.2 ± 4.5 vs. 6.3 ± 5.7 days, p = 0.4, systemic antibiotics alone vs. catheter exchange after initiation of antibiotic treatment, respectively).

Discussion

The native AV fistulas, followed by the synthetic AV grafts, are considered optimal long-term vascular accesses for patients on maintenance HD. However, some patients require dual-lumen, tunneled, cuffed HD catheters, either temporarily while awaiting maturation of a native AV fistula or development of a newly placed synthetic AV graft, or as a last resort due to lack of other long-term HD accesses.

Bacteremia is a common complication in HD patients with central HD catheters. These patients are typically treated with a 2- to 3-week course of parenteral antibiotics. Most nephrologists will attempt to salvage the HD
Routine Replacement of HD Catheter

We encountered 8 cases of paraspinal/vertebral infections, all of whom had HD access-associated bacteremia in the preceding 1–20 weeks. Catheter salvage had been attempted in these patients with systemic antibiotic therapy alone. Subsequently, we changed our protocol for the management of bacteremia in patients with tunneled, cuffed, HD catheters, i.e., the catheters were exchanged at ~48 h over a guide wire using the old tunnel or a new tunnel (if there was evidence of tunnel infection), as has been advocated before [9]. Following this change in our clinical practice, we did not encounter any new cases of paraspinal/vertebral infection(s) at our institution over the next 15-month period. This was in view of roughly the same number of bacteremic episodes (38 episodes over 20 months vs. 34 episodes over 15 months) and their microbiology (86.5 vs. 82% gram-positive staphylococci; 11 vs. 14% gram-negative bacilli; 2.5 vs. 4% yeast infection) in the two time periods. Thus, despite the similar incidence of de novo catheter-associated bacteremia in these two time periods, we noticed metastatic infectious complications in the former period when catheter salvage was routinely attempted with systemic antibiotics alone, potentially leading to more prolonged clinical or subclinical bacteremia. We also found a similar duration of hospitalization for the documented episodes of bacteremia in the two time periods, which suggests that subclinical and/or intermittent bacteremia in the former time period might have been responsible for the high incidence of paraspinal/vertebral infection in them.

In summary, our observation illustrates that HD access-associated bacteremia may result in serious complication of paraspinal/vertebral infection(s). The development of these metastatic infections may occur up to weeks after successful treatment of the original bacteremia. Thus, a new onset of back pain in a bacteremic or recently documented bacteremic HD patient should prompt diagnostic efforts to exclude this serious complication. Replacement or exchange of tunneled, cuffed catheters over a guide wire has helped us eliminate paraspinal/vertebral infections at our institution. Therefore, we strongly discourage the practice of catheter salvage with systemic antibiotics alone and recommend catheter replacement at ~48 h of systemic antibiotic therapy to prevent this potential infectious complication.
