Dear Sir,

The growing recognition of cervical manipulation as a treatment of neck pain and cervicogenic headaches has led to increased interest in potential complications that may result from this treatment approach. In 1947, Pratt-Thomas and Berger [1] reported 2 patients who died in less than 24 h after chiropractic treatment. Since their report, many authors have described patients with various neurological complications caused by cervical spine manipulations. Most of the patients described were relatively young, which probably reflects the age of people who seek this type of care. In this connection, complications mentioned most often are vertebral artery dissection and/or occlusion as well as consequential posterior circulation stroke [2]. To our knowledge, this is the first report of vertebral artery occlusion, cerebellar infarction and obstructive hydrocephalus as a result of cervical spine manipulation.

Case Report

The patient was a 46-year-old non-smoking man with a previous history of neck pain. He was submitted to a complete checkup for life insurance purposes (including neurologist examination and carotid and vertebral artery color Doppler examination) 2 months before hospital admission, and the checkup results were normal. His personal and family anamnesis contained no information on risk factors of cerebrovascular disease nor any information on the existence of connective tissue disorder. Due to neck pain and cervicogenic headaches that lasted throughout several years, the patient was subjected to cervical spine manipulation.

The patient was admitted to hospital because of stitching interscapular pain accompanied by intense headache, nausea and vomiting which appeared 30 h following cervical manipulation. At admission to hospital, he was conscious and astatic. He had a severe horizontal nystagmus directed to the right and right-sided dysmetria. The Stewart-Holmes test (rebound phenomenon seen in cerebellar disorders) on the right arm was positive. His blood pressure was 140/80 mm Hg and other vital signs were normal.

Complete hematology, biochemistry and coagulation tests were normal. The following analyses were performed: complement level, complement components C3 and C4, circulating immune complexes in blood, antixtractable nuclear antigen, antineutrophil cytoplasmatic antibodies, antistaphylolysin antibodies, antistreptolysin O test, lupus erythematosus cells, rheumatoid factor, antinuclear factor, and cerebrospinal fluid, and the findings were all normal. Serologic studies for syphilis, hepatitis and HIV were negative.

ECG, chest radiography, fundus oculi, transthoracic echocardiogram, brain CT scan and contrast-enhanced CT scan of the thoracic aorta were normal as well. Carotid and vertebral artery color Doppler examination revealed right vertebral artery occlusion (from the V2 segment distally).

The cervical collar (‘Schanz’) was applied and analgetic (tramadol), antiemetic (thiethylperazine) and prophylactic anticoagulant (low-molecular-weight heparin) therapies were introduced. During the following hours, the patient’s vital functions were monitored. The values of blood pressure increased up to 230/130 mm Hg. Despite applied antiedematous (10% solution of mannitol) and antihypertensive therapy (urapidil), the patient’s intense headache and neck pain persisted. His state of consciousness worsened (Glasgow Coma Scale score = 6). Because of acute respiratory insufficiency, he was placed on mechanical ventilation. The control brain CT scan after 18 h showed an extensive right cerebellar infarction (fig. 1a) including consequential obstructive hydrocephalus (fig. 1b). A neurosurgical implantation of external ventricular drainage was urgently performed. Following the operation, multislice CT angiography was performed, which confirmed the occlusion of the right vertebral artery (fig. 2). Skin biopsy was not performed. External ventric-
ular drainage was removed after 3 months. Four months afterwards, the patient’s neurological examination showed mild right-sided dysmetria.

Discussion
Cervical spine manipulations take on the risk of many, potentially fatal neurological complications such as: vertebral artery dissection and/or occlusion [2], dissection and/or occlusion of the internal carotid artery [2, 3], occlusion of the basilar artery [4], posterior inferior cerebellar artery dissection [5], cerebellar and cerebral infarction [2], intracerebellar hematomata and obstructive hydrocephalus [6], brain stem infarction, for example, Wallenberg’s syndrome [7], Dégérine syndrome [8], ‘locked-in’ syndrome [9]. The occurrence of radiculopathy and myelopathy [10] is also a possibility as well as the occurrence of neuro-ophthalmological complications such as the Horner syndrome [2] and homonymous hemianopsia caused by occipital infarction [11]. Vascular complications are more frequent in the area of posterior (vertebrobasilar) than in the area of anterior circulation [10], and the vertebral artery dissection is especially important, most often localized at the level C1–C2 where the artery changes from its vertical course to a horizontal one [12].

It is difficult to estimate the incidence of spinal manipulative therapy complications, as they are probably underreported in the literature. Rothwell et al. [13] tested the association between recent cervical spine manipulation and vertebrobasilar accidents. They found that in the group of examinees younger than 45 years of age, vertebrobasilar dissection or occlusion was 5 times more likely than in controls. This corresponds to an incidence of 1.3 case of vertebrobasilar accidents among 100,000 individuals receiving cervical spine manipulation. A survey of 177 neurologists practicing in California revealed 55 strokes, 30 radiculopathies, and 16 myelopathies resulting from spine dissection during a 2-year period of time [10]. Spinal disk herniation or displacement of bony structures can result in spinal cord compression, radiculopathy, or cauda equina syndrome [10], but there is also a possibility of ischemic cervical myelopathy development in case of vertebral artery dissection [14].

In the case of multiple artery dissection, we must take into consideration a possible existence of connective tissue disorder such as the Marfan syndrome, the Ehlers-Danlos syndrome, fibromuscular dysplasia or cystic medial necrosis [3]. Predispositional factors for the development of complications from cervical spine manipulations are the following ones: advanced cervical spondylosis, atherosclerosis, stenosis of neck arteries, vasculitis (luteic arteritis), connective tissue disorder, congenital asymmetry of the posterior circulation and vertebrobasilar insufficiency [3, 5, 10].

In our patient, we did not find any risk factor despite extensive diagnostic examination and our opinion is that vertebral artery occlusion is a result of dissection caused by hyperextension and neck rotation during cervical manipulation. Application of a cervical collar is not a routine procedure in such cases, and our intention was to prevent further propagation of the dissection.

Before cervical spine manipulation, it would be recommendable to perform color Doppler ultrasound examination of carotid and vertebral arteries, transcranial color or Doppler imaging of the vertebrobasilar circulation and X-ray examination of the spine. It is impossible to completely exclude the risk of complication occurrence. The approach to each patient must be individual and in each separate case it is necessary to evaluate the benefit brought by cervical spine manipulation in relation to the potential risk that the patient is being exposed to.
