Abstract
We report a case of a chronic myeloid leukemia patient showing progressive bone marrow fibrosis and anemia during imatinib therapy. Given the loss of major molecular response, we switched treatment to dasatinib 100 mg daily, observing a reduction in BCR-ABL transcript, a significant improvement of anemia, and a gradual disappearance of fibrosis. After 7 years of dasatinib therapy the patient maintains a complete cytogenetic response and a deep molecular response; the last bone biopsy confirmed the absence of fibrosis.

Introduction
Chronic myeloid leukemia (CML) is a clonal myeloproliferative disorder that arises from a reciprocal balanced translocation between the long arms of chromosomes 9 and 22: t(9;22). The resulting Philadelphia chromosome...
Disappearance of Bone Marrow Fibrosis in CML with Dasatinib

Case Report

A 45-year-old male patient was admitted to our hematology department in 1995 with severe leukocytosis. A bone marrow biopsy revealed hypercellular bone marrow, with an increased ratio of myeloid/erythroid precursors, compatible with chronic myeloproliferative disorder. The bone marrow cytogenetic analysis revealed the presence of the Philadelphia chromosome in all metaphases, and the molecular examination was positive for the BCR-ABL transcript. A low-risk Sokal CML diagnosis was made and, in the pre-TKI era, therapy with interferon was started. During interferon therapy the patient achieved a complete hematological response associated with a reduction of the BCR-ABL transcript after 1 year. However, he never reached a major molecular response (MMR). Therefore, in October 2000, with the introduction of the first-generation TKI, the patient began treatment with imatinib 400 mg/day, obtaining an MMR after the first 3 months of therapy. However, in October 2006, the patient presented a progressive anemia, with a minimum hemoglobin (Hb) value of 7 g/dL. BCR-ABL monitoring still revealed an MMR associated with a complete cytogenetic response (CCyR). The patient started α-erythropoietin treatment at a weekly dose of 40,000 UI. Hb levels showed a progressive increase up to a maximum value of 11 g/dL. In May 2008, the patient experienced a new episode of severe anemia (Hb 8 g/dL), together with an on log increase of BCR-ABL transcript in the bone marrow (BCR-ABL IS% from 0.011 to 0.118), while he maintained a CCyR. The imatinib dose was increased to 600 mg/day. Due to the persistence of anemia (Hb 9 g/dL), in November 2008 the patient underwent a bone marrow biopsy, which clearly showed a fibrotic pattern (Fig. 1a, b). Cytogenetic analysis was negative for the presence of Philadelphia chromosome and/or other cytogenetic abnormalities, with a stable BCR-ABL transcript (BCR-ABL IS% = 0.199). In January 2009, a worsening of anemia (Hb 7 g/dL) was observed, which required red blood cell support. Notably, an increase in BCR-ABL transcript levels was documented (BCR-ABL IS% = 1.34) with loss of response.
Discussion

Since histopathology of the bone marrow had never been considered in the management of CML, there is a lack of long-term information about bone marrow histology and its variation during therapy. Bone marrow fibrosis in CML does not seem to be a rare event. It can be found in the bone marrow of about 30–40% of patients before treatment and has been shown to be associated with adverse prognosis, independently of other prognostic factors [2]. In fact, the worsening of bone marrow fibrosis during therapy is an early indicator of disease progression, which precedes the changes in the peripheral blood, the spleen size, or marrow burst counts [2]. To date, the exact pathophysiology of bone marrow fibrosis in CML is unknown, but it is believed to be secondary to cytokine release (transforming growth-factor-ß and platelet-derived growth factor, PDGF) by megakaryocytes and to an abnormal stimulation of fibroblasts [2]. Some studies have shown the ability of imatinib to induce a significant regression of bone marrow fibrosis in CML patients, which was paralleled by a marked decrease of megakaryocytes and a specific anti-PDGF effect, but was not correlated with a cytogenetic response [3, 4]. In fact, imatinib is not only an inhibitor of ABL, but was originally developed as a specific PDGF receptor inhibitor [5]. However, imatinib does not guarantee against the evolution of marrow fibrosis and showed modest activity in patients with primary myelofibrosis [6]. Dasatinib is a second-generation TKI with demonstrated clinical activity in all stages of CML; it is a dual SRC/ABL kinase inhibitor, is 325-fold more potent against BCR-ABL than imatinib, and has significant inhibitory activity against wild-type c-Kit and PDGF [7]. SRC kinases play important roles in the activation of fibroblasts and in the development of fibrosis [8].

Furthermore, since BCR-ABL seems to be implicated in the phosphorylation of STAT5, another hypothesis regarding the regression of marrow fibrosis is that dasatinib inhibits the JAK/STAT5 cascade that represents the classical pathway for marrow fibrosis treatment [9].

In our patient, bone marrow fibrosis anticipated the loss of both the molecular and cytogenetic responses during treatment with imatinib, confirming its role as an early indicator of disease evolution. Dasatinib therapy resulted in a rapid disappearance of fibrosis, suggesting its higher efficacy compared to imatinib. In fact, the ability to inhibit both SRC kinase and PDGF gives dasatinib a more potent antifibrotic effect. In our case, considering the platelet count settled between 150 and 250 × 10^9/L during the course of CML, it is unlikely that there was any relationship with bone marrow fibrosis. These findings offer novel therapeutic possibilities in diseases with abnormal bone marrow fibrosis.
